ABSTRACT

Objective: To prospectively compare the results of spot urine protein-creatinine (P/C) ratio with 24-hour urine protein excretion in women with preeclampsia.

Materials and Methods: A total of 76 pregnant women with preeclampsia were prospectively studied for proteinuria at CAIMS, Karimnagar for a period of one year from August 2013 to July 2014. Urine P/C ratio was determined in a spot midstream sample, and the amount of protein excretion was measured in 24-hour urine collected on the subsequent day. The correlation between the spot P/C ratio and 24-hour urine protein excretion was assessed.

Results: There was a strong correlation between the spot P/C ratio and 24-hour urine protein excretion (r = 0.84; P < .001). The optimal spot P/C ratio cut-off point was 0.20 for 300 mg/24 h of protein excretion (preeclampsia), with a sensitivity, specificity, positive predictive value, and negative predictive value of 91.2%, 87.8%, 94.4%, and 96.8%, respectively. A spot P/C ratio less than 0.19 could exclude preeclampsia with a sensitivity of 100%.

Conclusions: We found that there is a significant correlation between the spot urine P/C ratio and 24-hour urine protein excretion in women with preeclampsia. Urine P/C ratio could be used for exclusion of preeclampsia.

KEYWORDS: Urine protein: creatinine ratio, Preeclampsia, 24 hour urinary protein.

INTRODUCTION

Preeclampsia is defined as a systolic blood pressure level of 140 mm Hg or higher or a diastolic blood pressure level of 90 mm Hg or higher that occurs after 20 weeks of gestation with proteinuria [1]. Proteinuria is an important sign of preeclampsia, and diagnosis is questionable in its absence. Significant proteinuria is described as 300 mg or more of urine protein per 24-hour period. Measurement of protein excretion in a 24-hour urine collection has been the long-standing gold-standard but time consuming test for the quantitative evaluation of proteinuria induced by preeclampsia. A more rapid test capable of accurately predicting the results of a 24-hour
urine would be valuable. An alternative method for quantitative evaluation of proteinuria is the measurement of protein-creatinine (P/C) ratio in a spot urine sample, which avoids the influence of variations in urinary solute concentration and provides a more convenient and rapid method to assess protein excretion.

The measurement of a random urine protein-creatinine (P/C) ratio has been tested as a substitute for the 24-hour urine protein excretion test for quantifying protein excretion in patients with renal diseases, such as diabetic nephropathy, lupus nephritis, and transplanted kidneys, with good correlation between the two methods [2-6]. The method relies on calculating the ratio of spot urine protein excretion to creatinine excretion and can normalize the protein excretion to the glomerular filtration rate. Therefore, a random urine P/C ratio is not influenced by variations in hydration status [7]. However, because of the variety of the cutoff values among past studies [8-10], there is no uniform standard so the clinical usefulness of this test is still controversial.

The aim of the present study was to evaluate the ability of the random urine P/C ratio to predict significant proteinuria, as well as to introduce a diagnostic test for preeclampsia that would avoid the inconvenience and time consumption of 24-hour urine protein collection.

MATERIAL AND METHODS

Patients
Pregnant women who were admitted in our obstetrics department with a suspicion of preeclampsia were studied prospectively. The study was conducted at Chalmeda ananda rao institute of medical sciences, karimnagar, a tertiary care centre, between August 2013 and July 2014, and the local ethics committee approved the study design.

Preeclampsia was defined as a blood pressure of 140/90 mm Hg or higher after the 20th week of gestation measured twice at least 6 hours apart and a urine protein of 1+ or greater by dipstick test or chronic hypertension without proteinuria before the 20th week accompanied by new-onset urine protein of 1+ or greater by dipstick test. Women with the following conditions were excluded: a known kidney disease, bacteriuria, bed rest longer than 24 hours, and gestational diabetes mellitus. In addition, women who delivered their babies during the urine collection day were excluded. A total of 76 pregnant women meeting the inpatient admission criteria for the evaluation of preeclampsia were prospectively recruited and provided informed written consent.

Urine Tests
Urine was collected for 24 hours. Immediately prior to the collection period, the patients also provided a spot midstream urine sample. The urine P/C ratio was determined on spot urine specimens. The concentration of total protein in urine was measured by a biuret colorimetric assay and the urine creatinine level was measured by a modified Jaffe test. The urine P/C ratio was obtained by dividing the urinary protein concentration by the urine creatinine concentration. Measurements on the 24-hour urine sample were performed on the same day as collections were completed.

Statistical Analyses
The 24-hour urine protein excretion results were used as a gold standard in determining the cutoff points for the significant and severe proteinuria. Sensitivity, specificity, and positive and negative predictive values of random urine P/C ratio were also calculated against this standard. The receiver operating characteristic (ROC) curve was used, and the area under the curve (AUC) was calculated. The relationship between the urine P/C ratio and the 24-hour protein excretion was assessed with the Pearson correlation test. A P value less than .05 was considered significant.

RESULTS
A total of 114 pregnant women with preeclampsia were selected, of whom 38 were excluded because of gestational diabetes mellitus in 12, bacteriuria in 12, delivery before the completion of their 24-hour urine collection in 11, inadequate 24-hour urine collection in 3. Finally, 76 eligible pregnant women completed the study. Their mean age was 24.4 ± 3.2 years (range, 17 to 32 years). Four patients had pre-existing hypertension with superimposed preeclampsia.
G. Shreya et al.: Comparison of spot urine protein-creatinine ratio with 24-hour urine protein excretion in women with preeclampsia.

Their mean gestational age was $35.2 \pm 3.6$ weeks (range, 23 to 41 weeks). The median serum creatinine concentration was 0.62 mg/dl, and the mean urinary protein excretion in 24-hour urine collections was $1.79 \pm 0.80$ g/dl (range: 135 mg/dl to 3000 mg/dl).

The mean P/C ratio was $1.84 \pm 0.91$ (range, 0.42 to 3.58). The correlation coefficient for the P/C ratio against the 24-hour urine protein excretion was 0.84. The regression equation was $Y = 0.81 X + 0.3$ (P < .001; Figure) where Y indicates urinary protein excretion (g/24 h) and X indicates P/C ratio. By the ROC curve analysis, the P/C ratio of 0.20 was identified as the best threshold to detect urine protein excretion of 300 mg/24 h, with sensitivity and a specificity of 91.2% and 87.8%, respectively. The positive and negative predictive values for P/C ratios 0.20 were 94.4% and 96.8%, respectively. A spot P/C ratio less than 0.19 could exclude preeclampsia with a sensitivity of 100%.

**DISCUSSION**

Preeclampsia is a significant contributor to maternal mortality and it affects 2% to 8% of all pregnancies [11]. One of the ways to diagnose preeclampsia, apart from the blood pressure criteria, is to look for the presence of significant proteinuria.

Several methods are available for measuring proteinuria but 24-hour urine protein excretion has long been regarded as the gold standard. However, this test has some disadvantages such as inconvenience for patients, inaccuracy due to incomplete collection, cost, and delay of diagnosis and management, which makes its wide use difficult for clinicians. One of the other methods most commonly used is the urinary dipstick test because of its simplicity and low cost. Nevertheless, this method has high false positive and false negative result rates associated with fluctuations throughout the day due to water intake, exercise, diet, posture, or improperly trained laboratory staff [12-14]. Thus a more rapid and accurate diagnostic test that is capable of predicting 24-hour urine protein excretion would be valuable.

Here, we propose the use of random urine P/C ratio to facilitate prompt decision making by clinicians [15-16]. We prospectively determined the correlation between spot urine P/C ratio and 24-hour urine protein excretion. Urine was collected from patients who met admission criteria for preeclampsia, and the spot value obtained at the beginning of the 24-hour collection period was compared to the result acquired from the 24-hour collection to see if these values were correlated. A good correlation between the spot urine P/C ratio and 24-hour protein excretion has been demonstrated in patients with diabetic nephropathy, lupus nephritis, chronic kidney disease, and transplanted kidneys [3-6]. The National Kidney Foundation guidelines have suggested that spot urine samples should be used to detect and monitor proteinuria in children and adults [11].

In our study, a urine P/C ratio of 0.20 corresponded with a protein excretion rate of 300 mg/24 h. These are characterized by excellent accuracy. Consistent with most previous studies with correlation coefficients ranging between 0.80 and 0.97, we found a strong correlation ($r = 0.84$) between the spot P/C ratio and the 24-hour urine protein [12, 17-19]. However, using the spot P/C ratio of 0.20 as a correlate to the critical value of 300 mg of protein over 24 hours would result in the failure to identify significant proteinuria in approximately 8.8% of affected patients.

There are some reports with conflicting results. Because of the variability in laboratory methods for measuring proteinuria in different reported studies, several cut-off points and different units for the urinary P/C ratio have been reported, thereby precluding valid comparisons among such studies [8-10].
Three systematic reviews have evaluated literature and have come to similar conclusions [20].

In an analysis by Cote et al, the spot P/C ratio had a pooled sensitivity of 83.6% and specificity of 76.3% using a cut off of 0.26 to predict proteinuria > 300mg/day in a 24 hour collection, concluding that P/C is a reasonable rule out test for excluding proteinuria [21].

Papanna et al, in an analysis suggested that a lower cut off of 0.13 0.15 provides higher sensitivity but with more false positive results. A higher cut off of 0.6 to 0.7 had a higher specificity for significant proteinuria, but at a cost of lower sensitivity. Midrange ratios had poor sensitivity and specificity [22].

A more recent meta-analysis by Morris RK et al including 2790 women had similar findings: a single diagnostic threshold of 0.3 had a sensitivity and specificity of 81% and 76% respectively. A lower cut off (0.13) had better (89%) sensitivity for exclusion of proteinuria [23].

Taken together, these data suggest that a urine P/C ratio >0.7 strongly predicts significant proteinuria whereas a P/C ratio <0.15 can be considered normal, so confirmation with 24 hour urine collection probably isn’t necessary in these individuals [24]. If a 24 hour urine collection is not obtained, guidelines define proteinuria as random urine P/C ratio >0.26.

Our data suggested that the random urine P/C ratio is a highly accurate test for discriminating between insignificant and significant proteinuria, as demonstrated by an area under the ROC curve of 0.92. The main concern in clinical use of this test is the false-negative test results, because 8% of patients with preeclampsia may be missed. To obtain the optimal cut-off, we selected the one that while increasing specificity maintains a sensitivity of higher than 90% in order to reduce the possibility of missing the diagnosis of preeclampsia.

Research in the future should be focused on the evaluation of clinical outcomes and the cost-effectiveness of the use of a random urinary P/C ratio for prediction of significant proteinuria. In addition, studying the test in an outpatient basis should be further considered in order to apply it in ambulatory management of preeclamptic patient. We suggest that further evaluations be done in order to determine a cut-off value for prediction of mild preeclampsia.

**CONCLUSION**

Based on the results of our study, we conclude that random urine P/C ratios can predict 24-hour urine protein excretion with a high accuracy. This test can also be used as a reasonable alternative to 24-hour urine protein excretion, especially in emergency situations, and, it could also complement the urinary dipstick test in preeclamptic pregnancy.
